Circuit for SHA-1

by Damian Cisneros

CPE 405

The SHA cryptographic hash functions have been used for Internet security for over 20 years. It generates a message or key based on the message it is given. That key is then used to secure passwords without saving the password itself. Another application of it is to use it to authenticate PDF copies by comparing the key attached to the PDF to the key the publisher generates with their message. It can be considered a one-way encryption that cannot be decoded. The SHA-1 published in 1995 is still used today even though it has been cracked by Google. Google has been pushing websites to use the newer SHA-2 and SHA-3 which are much more secure. I decided to do my project on the SHA-1 since I wanted to understand more about Internet security.

Before going into the algorithm, I will explain a bit of how the SHA-1 function works based on the paper published by the NSA on the SHA-1. The function takes in a message in string from 0 length to 2^64 bit length. It splits that message into 512-bit blocks, this process is called message padding. In the algorithm there is an initial state or 5-word buffer named H0, H1, H2, H3, and H4 each being 32-bit. This state is initialized based on constants they defined. There is also another 5-word buffer which is used inside the compression function, A, B, C, D, and E. It then runs its compression function, which repeats 80 times. Inside the function, it is taking in parts of the message and doing a series of logical operations such as AND, XOR, and ORs to randomize the message. At the end of each iteration, it is adding the result to the state buffer of H0-H4. When it is done with iterations, the result in the state buffer H0-H4 is the 160-bit unique message or also known as key that was generated. If at this point there is another block of data, it will repeat the same steps except this time it will use the state buffer that the previous block generated as the initial state rather than the constants they defined.

A much simpler way to explain this process is to visualize it as a washing machine. The hash function would be the inside of the machine and your message would be clothing. If you were to add clothing one at a time in a certain order, then pausing and adding more clothing as the wash continues, at the end you will have mixed order of clothing.

The approach I wanted to take was what goes on inside the machine where the message is mixed and for one 512-bit block. The message padding is what I did by hand and the data I put in my testbench to send to the machine or compression function. I had two modules for my SHA-1 algorithm. One(sha_1.v)was for where my initializing values, constants, and where I did the logic operations. The other module(sha1_logic) for generating the new A-E values after each iteration with the data received which had its logic for that iteration already done.

As for my results which I tested with the string "abc," I would generate an incorrect hash of b2b5619fc6086elcafbce4a767e18f47ef590c43 when a9993e364706816aba3e25717850c26c9cd0d89d was expected. After simulation, I noticed that my C and D values were incorrect because they were the same(shown in the waveform below)

which is not supposed to be the case based on the algorithm. My error I believe is in grabbing the wrong bits in the buffer for C and D. I checked my code to make sure that I did not grab the same exact bits but did not make that mistake. It would take a longer look at the simulation results to find where exactly the issue happened. After this project, I believe I have learned a bit more of Internet security and what goes on behind the scenes. I would like to continue studying Internet security and taking courses for it.
